Accelerated intersection of geometric objects *

Alberto Paoluzzi

October 1, 2015

Abstract

This module contains the first experiments of a parallel implementation of the intersection of (multidimensional) geometric objects. The first installment is being oriented to the intersection of line segment in the 2D plane. A generalization of the algorithm, based on the classification of the containment boxes of the geometric values, will follow quickly.

*This document is part of the *Linear Algebraic Representation with CoChains* (LAR-CC) framework [CL13]. October 1, 2015

1 Introduction

An easily parallelizable implementation of the accelerated intersection of geometric objects is given in this module. Our first aim is to implement a specialized version for simplices, that generalizes the nD-trees of points (that are 0-simplices), to $(d-1)$-dimensional simplices in d-space, starting with the intersection of line segments in the plane. Our plan is to follow with an implementation for intersection of general convex sets.

2 Implementation

The first implementation of this module concerns the computation of the intersection points among a set of line segment in the 2D plane. The containment boxes of the input segments are iteratively classified against the 1-dimensional centroid of smaller and smaller buckets of data.

At the end of the classification, where the same geometric object may be inserted in several different buckets, a *brute-force* intersection is applied to each final subset. Finally, the duplicated intersection points are removed, and a 1-dimensional LAR data structure is generated, with 1-cells given by the split line segments.

A complete LAR of the plane partition generated by the arrangment of lines is then computed by: (a) generating the maximal 2-connected components of such 1-dimensional graph; and (b) by traversing in counter-clockwise order the generated subgraphs to report the 2-dimensional cells of the plane partition.

The splitting algorithm may be easily parallelized, since both during their generation and at the end of this one, the various buckets of data can be dispatched to different processors for independent computation, followed by elimination of duplicates. In particular, a standard *map-reduce* software infrastructure may be used for this parallelization purpose.

2.1 Construction of independent buckets

Containment boxes Given as input a list `randomLineArray` of pairs of 2D points, the function `containment2DBoxes` returns, in the same order, the list of *containment boxes* of the input lines. A *containment box* of a geometric object of dimension d is defined as the minimal d-cuboid, equioriented with the reference frame, that contains the object. For a 2D line it is given by the tuple $(x1, y1, x2, y2)$, where $(x1, y1)$ is the point of minimal coordinates, and $(x2, y2)$ is the point of maximal coordinates.

⟨ Containment boxes 2a ⟩ ≡

2.3 Generation of LAR representation of split segments

The function `lines2lar` is used to generate a 1-dimensional LAR complex from an array of lines, i.e. of pairs of 2D points. For every *line* in `frags` is computed an *ordered* list `outline` of *symbolic* intersection points, including the first and last vertex of the line, and every interior point generated by the list `params[k]`.

Then, for every symbolic representation `key` of a point in `outline`, a dictionary vertex is either created or retrieved, and a corresponding edge is orderly created, using the index of the point. At the same time, the vertices created in this way are accumulated within the `V` array. Finally, each edge in EV is extended to contain a second vertex index using the subsequent edge.

The third stage finalizes the vertex set of the output LAR, by identifying the closest vertices, i.e. those at distance less or equal to the current resolution, set to `10**(-PRECISION)`, by searching via the `scipy.spatialKDTree` the pairs of vertices at less than this distance.

A fourth stage identifies the possibly duplicated edges. Some of these could appear, e.g., when importing a set of adjacent boxes from some drawing program, to generate an array of lines, to be mutually intersected and transformed into a LAR data structure.

Create the LAR of fragmented lines

⟨ Create the LAR of fragmented lines 6 ⟩ ≡

2.5 2D cells from biconnected components

It is very easy, using the LAR representation of topology, to compute the 2-cells of the plane partitions (see Figures 1b and 1c) induced by the biconnected components extracted from a graph (1-complex).

In particular, let us consider the CSR (Compressed Sparse Row) representation of the characteristic matrix M_1, here usually denoted as `EV`, in order to remark that we represent the edges on the rows, and the vertices on the columns of the matrix. As such it is a binary matrix. So, we can readily reconstruct the topology of 2-cells by associating to each non-zero (sparse) matrix element $\texttt{angle\_EV}(h, k)$ the angle in radians that the edge e_h forms with the orizontal line, when it incides on the vertex v_k.

Of course, if $e_h = (v_{k_1}, v_{k_2})$, then it will be

$$\texttt{angle\_EV}(h, k_2) = \texttt{angle\_EV}(h, k_1) + \pi = -\texttt{angle\_EV}(h, k_1)$$

Therefore, the columns of `angle_EV`, i.e. the rows of $\texttt{angle\_VE} := \texttt{angle\_EV}^t$, after being sorted on their angles α, and associated with the angle differences $\Delta\alpha$, will provide a basis of elementary $1-$*cochains* that evaluate to zero for each closed 1-cochain, i.e. for every cycle supported by the linear space of 1-chains on the given line arrangment.

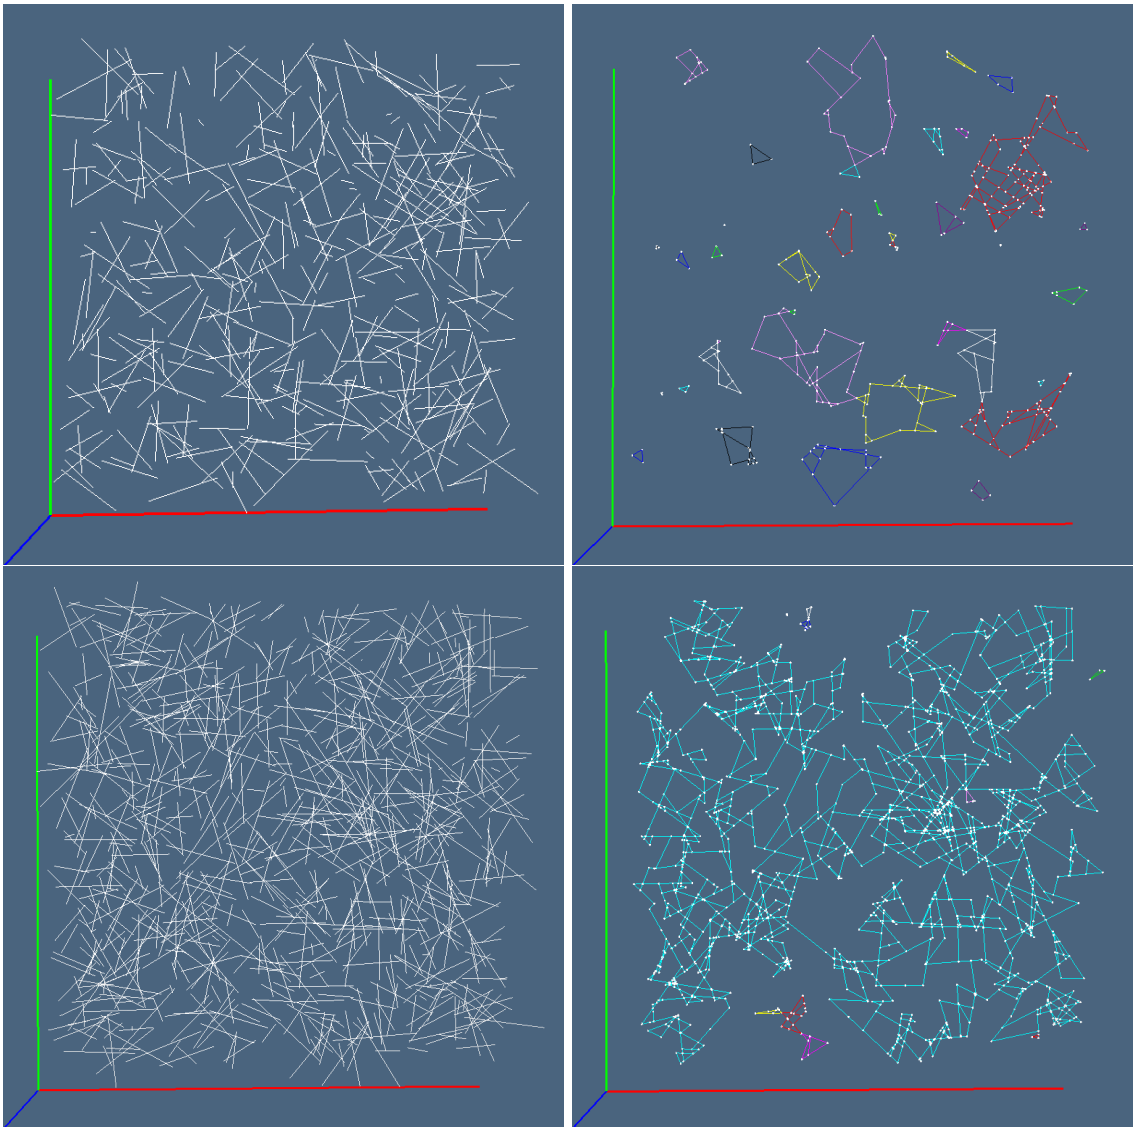

Figure 1: Two random line arrangements, and the biconnected components extracted by their LAR 1-complexes.

Slope of edges

Circular ordering of edges around vertices

⟨ Slope of edges 9 ⟩ ≡

```
""" Circular ordering of edges around vertices """
def edgeSlopeOrdering(model):
    V,EV = model

Ordered incidence relationship vertices to edges As we have seen, the `VE_angle` list of lists reports, for every vertex in `V`, the list of incident edges, *counterclockwise ordered* around the vertex. Therefore the `ordered_csrVE` function, given below, returns the "compressed sparse row" matrix, row-indexed by vertices and column-indexed by edges, and such that in position (v, e) contains the index ℓ of the next edge (after e, say) in the counterclockwise ordering of edges around v.

⟨ Ordered incidence relationship of vertices and edges 11a ⟩ ≡

```
""" Ordered incidence relationship of vertices and edges """

Txample The *ordered* `csrVE` (vertex-edge) matrix generated by the example of file `test/py/inters/test07.py` is shown in dense format in the example script below. Let us notice the each non-zero element $\texttt{csrVE}(k, h)$ stores the index of the previous edge inciding on the vertex v_k *before* the edge e_h. The traversal of the data structure is made accordingly, in order to extract the vertices of all the faces (minimal edge cycles) generated by a line arrangement in the plane.

⟨ Example of VE matrix with nextEdge indices 13a ⟩ ≡

```
csr2DenseMatrix(csrVE)
>>> array([
    [12,  0,  0,  0,  0,  0,  0,  0,  0,  0,  0,  0, 11,  0,  0,  0],
    [ 1,  2,  0,  0,  0,  0,  0,  0,  0,  0,  0,  0,  0,  0,  0,  0],
    [ 0, 14,  0,  0,  0,  0,  0,  0,  0,  0,  0,  0,  0,  0,  1,  0],

Transformation of an array of lines in a 2D LAR complex The whole transformation of an array of lines into a two-dimensional `LAR` complex is executed by the function `larFromLines`. The function returns the model triple `V,FV,EV`. The last element in `FV` is the *ordered* boundary chain. just notice that

⟨ Transformation of an array of lines in a 2D LAR complex 13b ⟩ ≡

```
""" Transformation of an array of lines in a 2D LAR complex """
def larFromLines(lines):
    V,EV = lines2lar(lines)
    V,EVs = biconnectedComponent((V,EV))
    EV = list(set(AA(tuple)(AA(sorted)(max(EVs, key=len)))))  ## NB
    V,EV = larRemoveVertices(V,EV)
    V,FV,EV = facesFromComps((V,EV))
    areas = integr.surfIntegration((V,FV,EV))
    boundaryArea = max(areas)
    interiorFaces = [FV[f] for f,area in enumerate(areas) if area!=boundaryArea and len(areas)
    boundaryFace = FV[areas.index(boundaryArea)]
    return V,interiorFaces+[boundaryFace],EV
```

2.6 Pruning LAR models from parts out of proper resolution

Pruning of clusters of too close vertices is executed by taking a LAR model as input, executing the following computations, and producing a new simplified LAR model.

Pruning away clusters of close vertices First, reduce the array of vertices `pts` to its *quotient set* with respect to the transitive closure of the relation of "nearness". Two vertices are "near" when their (Euclidean) distance is less than a given `RADIUS`. The subgraphs of the graph of this relation are *contracted* in a single point, set to the centroid of the vertices of the subgraph. The function `W` takes as input the array `pts` of vertex points, and returns: (a) the array `newV` of new vertices; (b) the list of lists `close` of sorted indices of pairs of close vertices, removed from duplicates; (c) the list of `clusters` of `pts` indices; (d) the integer `vmap` array, mapping old vertex indices to new vertex indices.

⟨ Pruning away clusters of close vertices 14 ⟩ ≡

```
""" Pruning away clusters of close vertices """
from scipy.spatial import cKDTree

def pruneVertices(pts,radius=0.001):
   tree = cKDTree(pts)
   a = cKDTree.sparse_distance_matrix(tree,tree,radius)
   print a.keys()
   close = list(set(AA(tuple)(AA(sorted)(a.keys()))))
   import networkx as nx
   G=nx.Graph()
   G.add_nodes_from(range(len(pts)))
   G.add_edges_from(close)
```

```
   clusters, k, h = [], 0, 0

   subgraphs = list(nx.connected_component_subgraphs(G))
   V = [None for subgraph in subgraphs]
   vmap = [None for k in xrange(len(pts))]
   for k,subgraph in enumerate(subgraphs):
      group = subgraph.nodes()
      if len(group)>1:
         V[k] = CCOMB([pts[v] for v in group])
         for v in group: vmap[v] = k
         clusters += [group]
      else:
         oldNode = group[0]
         V[k] = pts[oldNode]
         vmap[oldNode] = k
   return V,close,clusters,vmap
```
◇

Export a simplified LAR model Next, update the arrays of compressed characteristic matrices of a Linear Algebraic Representation. The standard approach is to read row-wise the arrays of matrices of incidence of cells on vertices; translate every index using the `vmap` array, mapping old vertex indices to new ones; remove repeated indices and substitute them with a single instance; check if the new index list has lenght greater or equal to the number of vertices of the simplex of the proper dimension. Finally, write an output cell if and only if the previous test is true.

⟨ Return a simplified LAR model 15a ⟩ ≡

```
""" Return a simplified LAR model """
def larSimplify(model,radius=0.001):
   if len(model)==2: V,CV = model
   elif len(model)==3: V,CV,FV = model

Test of pruning clusters of close vertices Here a list of random 2D points is generated. Then the set of vertices is pruned by updating it to its quotient set with respect to the transitive closure of a relation of "nearness" within an Euclidean distance of given `RADIUS`. The pruning of vertices is performed by the `pruneVertices` function, with input the array `pts` of points. The dictionary `vmap`

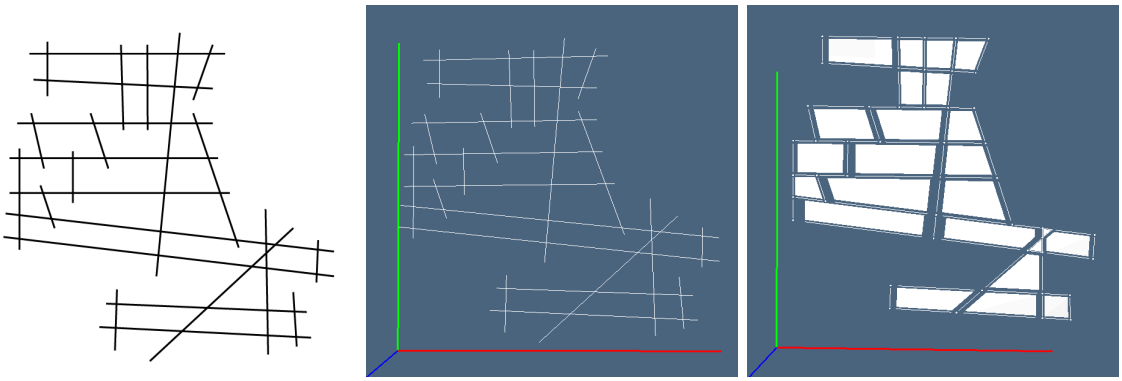

Figure 6: `LAR` complex generation from `SVG` file. (a) the input set of lines; (b) imported in `pyplasm` environment; (c) the extracted *regularized* 2-complex, drawn exploded.

SVG input parsing and transformation We postulate here that the input file `test/py/inters/test.svg` should contain only `<line>` primitives, so we skip any other content. Such primitives are parsed by matching against regular expressions, and their `x1,y1,x2,y2` attributes are extracted and stored into the `lines` variable. An isomorphic window-viewport transformation

is then performed, to transform the data within the standard unit 2D square $[0,1]^2$. The input vertices are finally set to a fixed resolution, using the `vcode` function.

⟨ SVG input parsing and transformation 24 ⟩ ≡

2-complex extraction from svg file The input `lines` arrangments produces a 1-dimensional complex stored into the `LAR` model `V,EV`. Then the *dangling edges* are removed from `EV_`, and the whole data set is renumbered, in order to remove the unused vertices, using the `larRemoveVertices` function. Finally the 2-cells are computed and stored in `FV`, and the positive areas of every 2cells are computed, so allowing for identify and removal of the exterior face, corresponding to the boundary of the complex. The polygonal boundary of the complex is finally drawn.

A Code utilities

Coding utilities Some utility fuctions used by the module are collected in this appendix. Their macro names can be seen in the below script.

⟨ Coding utilities 28a ⟩ ≡

```
    """ Coding utilities """
```

⟨ Generation of a random point 29a ⟩
⟨ Generation of a random line segment 29b ⟩
⟨ Transformation of a 2D box into a closed polyline 29c ⟩

⟨ Computation of the 1D centroid of a list of 2D boxes 29d ⟩
⟨ Pyplasm XOR of FAN of ordered points 30 ⟩
◇

Macro referenced in 16b.

Generation of random lines The function `randomLines` returns the array `randomLineArray` with a given number of lines generated within the unit 2D interval. The `scaling` parameter is used to scale every such line, generated by two randow points, that could be possibly located to far from each other, even at the distance of the diagonal of the unit square.

The arrays `xs` and `ys`, that contain the x and y coordinates of line points, are used to compute the minimal translation `v` needed to transport the entire set of data within the positive quadrant of the 2D plane.

⟨ Generation of random lines 28b ⟩ ≡

```
""" Generation of random lines """
def randomLines(numberOfLines=200,scaling=0.3):
    randomLineArray = [redge(scaling) for k in range(numberOfLines)]
    [xs,ys] = TRANS(CAT(randomLineArray))[:2]
    xmin, ymin = min(xs), min(ys)
    v = array([-xmin,-ymin])
    randomLineArray = [[list(v1[:2]+v), list(v2[:2]+v)] for v1,v2 in randomLineArray]
    return randomLineArray
```

◇

Macro referenced in 16b.

Generation of a random point A single random point, codified in floating point format, and with a fixed (quite small) number of digits, is returned by the `rpoint()` function, with no input parameters.

⟨ Generation of a random point 29a ⟩ ≡

```
""" Generation of a random point """
def rpoint():
    return eval( vcode([ random.random(), random.random() ]) )
```

◇

Macro referenced in 28a.

Generation of a random line segment A single random segment, scaled about its centroid by the `scaling` parameter, is returned by the `redge()` function, as a tuple ot two random points in the unit square.

⟨ Generation of a random line segment 29b ⟩ ≡

```
""" Generation of a random line segment """
def redge(scaling):
    v1,v2 = array(rpoint()), array(rpoint())
    c = (v1+v2)/2
    pos = rpoint()
    v1 = (v1-c)*scaling + pos
    v2 = (v2-c)*scaling + pos
    return tuple(eval(vcode(v1))), tuple(eval(vcode(v2)))
◇
```

Macro referenced in 28a.

Transformation of a 2D box into a closed polyline The transformation of a 2D box into a closed rectangular polyline, given as an ordered sequwncw of 2D points, is produced by the function `box2rect`

⟨ Transformation of a 2D box into a closed polyline 29c ⟩ ≡

```
""" Transformation of a 2D box into a closed polyline """
def box2rect(box):
    x1,y1,x2,y2 = box
    verts = [[x1,y1],[x2,y1],[x2,y2],[x1,y2],[x1,y1]]
    return verts
◇
```

Macro referenced in 28a.

Computation of the 1D centroid of a list of 2D boxes The 1D `centroid` of a list of 2D boxes is computed by the function given below. The direction of computation (either x or y) is chosen depending on the value of the `xy` parameter.

⟨ Computation of the 1D centroid of a list of 2D boxes 29d ⟩ ≡

```
""" Computation of the 1D centroid of a list of 2D boxes """
def centroid(boxes,coord):
    delta,n = 0,len(boxes)
    ncoords = len(boxes[0])/2
    a = coord%ncoords
    b = a+ncoords
    for box in boxes:
        delta += (box[a] + box[b])/2
    return delta/n

◇
```

Macro referenced in 28a.

Pyplasm XOR of FAN of ordered points

⟨ Pyplasm XOR of FAN of ordered points 30 ⟩ ≡

```
"""" XOR of FAN of ordered points """"
def FAN(points):
   pairs = zip(points[1:-2],points[2:-1])
   triangles = [MKPOL([[points[0],p1,p2],[[1,2,3]],None]) for p1,p2 in pairs]
   return XOR(triangles)

if __name__=="__main__":
    pol = [[0.476,0.332],[0.461,0.359],[0.491,0.375],[0.512,0.375],[0.514,0.375],
    [0.527,0.375],[0.543,0.34],[0.551,0.321],[0.605,0.314],[0.602,0.307],[0.589,
    0.279],[0.565,0.244],[0.559,0.235],[0.553,0.227],[0.527,0.239],[0.476,0.332]]

    VIEW(EXPLODE(1.2,1.2,1)(FAN(pol)))
```
