# 1 Introduction

# 2 Merging arguments

### 2.1 Reordering of vertex coordinates

A global reordering of vertex coordinates is executed as the first step of the Boolean algorithm, in order to eliminate the duplicate vertices, by substituting duplicate vertex copies (coming from two close points) with a single instance.

Two dictionaries are created, then merged in a single dictionary, and finally split into three subsets of (vertex,index) pairs, with the aim of rebuilding the input representations, by making use of a novel and more useful vertex indexing.

The union set of vertices is finally reordered using the three subsets of vertices belonging (a) only to the first argument, (b) only to the second argument and (c) to both, respectively denoted as  $V_1, V_2, V_{12}$ . A top-down description of this initial computational step is provided by the set of macros discussed in this section.

```
 \begin{tabular}{ll} $\langle$ Place the vertices of Boolean arguments in a common space 1$\rangle$ $\equiv$ $"""$ First step of Boolean Algorithm """$ $\langle$ Initial indexing of vertex positions 2$\rangle$ $\langle$ Merge two dictionaries with keys the point locations 3a$\rangle$ $\langle$ Filter the common dictionary into three subsets 3b$\rangle$ $\langle$ Compute an inverted index to reorder the vertices of Boolean arguments 4a$\rangle$ $\langle$ Return the single reordered pointset and the two $d$-cell arrays 4b$\rangle$$ $\Rightarrow$$
```

Macro referenced in 16b.

#### 2.1.1 Re-indexing of vertices

Initial indexing of vertex positions The input LAR models are located in a common space by (implicitly) joining V1 and V2 in a same array, and (explicitly) shifting the vertex indices in CV2 by the length of V1.

```
⟨Initial indexing of vertex positions 2⟩ ≡
    from collections import defaultdict, OrderedDict
    """ TODO: change defaultdict to OrderedDefaultdict """
    class OrderedDefaultdict(collections.OrderedDict):
        def __init__(self, *args, **kwargs):
```

```
if not args:
            self.default_factory = None
        else:
            if not (args[0] is None or callable(args[0])):
                raise TypeError('first argument must be callable or None')
            self.default_factory = args[0]
            args = args[1:]
        super(OrderedDefaultdict, self).__init__(*args, **kwargs)
   def __missing__ (self, key):
        if self.default_factory is None:
            raise KeyError(key)
        self[key] = default = self.default_factory()
        return default
   def __reduce__(self): # optional, for pickle support
        args = (self.default_factory,) if self.default_factory else tuple()
        return self.__class__, args, None, None, self.iteritems()
def vertexSieve(model1, model2):
  from lar2psm import larModelBreak
  V1,CV1 = larModelBreak(model1)
  V2,CV2 = larModelBreak(model2)
  n = len(V1); m = len(V2)
   def shift(CV, n):
     return [[v+n for v in cell] for cell in CV]
   CV2 = shift(CV2,n)
```

Merge two dictionaries with point location as keys Since currently CV1 and CV2 point to a set of vertices larger than their initial sets V1 and V2, we index the set V1  $\cup$  V2 using a Python defaultdict dictionary, in order to avoid errors of "missing key". As dictionary keys, we use the string representation of the vertex position vector provided by the vcode function given in the Appendix.

```
⟨ Merge two dictionaries with keys the point locations 3a⟩ ≡

vdict1 = defaultdict(list)
for k,v in enumerate(V1): vdict1[vcode(v)].append(k)

vdict2 = defaultdict(list)
for k,v in enumerate(V2): vdict2[vcode(v)].append(k+n)

vertdict = defaultdict(list)
for point in vdict1.keys(): vertdict[point] += vdict1[point]
```

**Example of string coding of a vertex position** The position vector of a point of real coordinates is provided by the function vcode. An example of coding is given below. The *precision* of the string representation can be tuned at will.

```
>>> vcode([-0.011660381062724849, 0.297350056848685860])
'[-0.0116604, 0.2973501]'
```

Filter the common dictionary into three subsets Vertdict, dictionary of vertices, uses as key the position vectors of vertices coded as string, and as values the list of integer indices of vertices on the given position. If the point position belongs either to the first or to second argument only, it is stored in case1 or case2 lists respectively. If the position (item.key) is shared between two vertices, it is stored in case12. The variables n1, n2, and n12 remember the number of vertices respectively stored in each repository.

Compute an inverted index to reorder the vertices of Boolean arguments The new indices of vertices are computed according with their position within the storage repositories case1, case2, and case12. Notice that every item[1] stored in case1 or case2 is a list with only one integer member. Two such values are conversely stored in each item[1] within case12.

 $\langle$  Compute an inverted index to reorder the vertices of Boolean arguments 4a $\rangle$   $\equiv$ 

```
invertedindex = list(0 for k in range(n+m))
for k,item in enumerate(case1):
   invertedindex[item[1][0]] = k
for k,item in enumerate(case12):
   invertedindex[item[1][0]] = k+n1
   invertedindex[item[1][1]] = k+n1
for k,item in enumerate(case2):
   invertedindex[item[1][0]] = k+n1+n2
```

>

### 2.1.2 Re-indexing of d-cells

Return the single reordered pointset and the two d-cell arrays We are now finally ready to return two reordered LAR models defined over the same set V of vertices, and where (a) the vertex array V can be written as the union of three disjoint sets of points  $C_1, C_{12}, C_2$ ; (b) the d-cell array CV1 is indexed over  $C_1 \cup C_{12}$ ; (b) the d-cell array CV2 is indexed over  $C_{12} \cup C_{2}$ .

The vertexSieve function will return the new reordered vertex set  $V = (V_1 \cup V_2) \setminus (V_1 \cap V_2)$ , the two renumbered s-cell sets CV1 and CV2, and the size len(case12) of  $V_1 \cap V_2$ .

 $\langle$  Return the single reordered pointset and the two d-cell arrays 4b $\rangle \equiv$ 

Macro referenced in 1.

#### 2.1.3 Example of input with some coincident vertices

In this example we give two very simple LAR representations of 2D cell complexes, with some coincident vertices, and go ahead to re-index the vertices, according to the method implemented by the function vertexSieve.

**Example discussion** The aim of the vertexSieve function is twofold: (a) eliminate vertex duplicates before entering the main part of the Boolean algorithm; (b) reorder the input representations so that it becomes less expensive to check whether a 0-cell can be shared by both the arguments of a Boolean expression, so that its coboundaries must be eventually split. Remind that for any set it is:

$$|A \cup B| = |A| + |B| - |A \cap B|.$$

Let us notice that in the previous example

$$|V| = |V_1 \cup V_2| = 12 \le |V_1| + |V_2| = 6 + 9 = 15,$$

and that

$$|V_1| + |V_2| - |V_1 \cup V_2| = 15 - 12 = 3 = |C_{12}| = |V_1 \cap V_2|,$$

where  $C_{12}$  is the subset of vertices with duplicated instances.

Macro never referenced.

Notice also that V has been reordered in three consecutive subsets  $C_1, C_{12}, C_2$  such that CV1 is indexed within  $C_1 \cup C_{12}$ , whereas CV2 is indexed within  $C_{12} \cup C_2$ . In our example we have  $C_{12} = \{3,4,5\}$ :

 $\langle$  Reordering of vertex indexing of cells 5c $\rangle$   $\equiv$ 

```
>>> sorted(CAT(CV1))
[0, 1, 1, 2, 3, 4, 5, 5]
>>> sorted(CAT(CV2))
[3, 4, 5, 6, 7, 7, 8, 8, 9, 10, 11]
```

Macro never referenced.

Cost analysis Of course, this reordering after elimination of duplicate vertices will allow to perform a cheap O(n) discovering of (Delaunay) cells whose vertices belong both to V1 and to V2. Actually, the same test can be now used both when the vertices of the input arguments are all different, and when they have some coincident vertices. The total cost of such pre-processing, executed using dictionaries, is  $O(n \ln n)$ .

#### 2.1.4 Example

### Building a covering of common convex hull

```
⟨ Building a covering of common convex hull 6a⟩ ≡

def covering(model1,model2):
    V, CV1, CV2, n12 = vertexSieve(model1,model2)
    _,EEV1 = larFacets((V,CV1),dim=2,emptyCellNumber=1)
    _,EEV2 = larFacets((V,CV2),dim=2,emptyCellNumber=1)
    CV1 = CV1[:-1]
    CV2 = CV2[:-1]
    VV = AA(LIST)(range(len(V)))
    return V,[VV,EEV1,EEV2,CV1,CV2],n12
```

Macro referenced in 16b.

   print "\ntasks =",tasks
   return tasks
```

facet-cell trivial intersection filtering A final filtering is applied to the pairs (cutting-Hyperplane, polytope in the tasks array, in order to remove those facets (pairs in 2D) whose intersection reduces to a single point, i.e. to the comman vertex between the boundary (d-1)-face, having cuttingHyperplane as affine hull, and the polytope d-cell.

For this purpose, it is checked that at least one of the facet vertices, transformed into the common-vertex-based coordinate frame, have all positive coordinates. This fact guarantees the existence of a non trivial intersection between the (d-1)-face and the d-cell.

```
\langle Trivial intersection filtering """

```

# 4 Splitting cells traversing the boundaries

In the previous section we computed a set of "slitting seeds", each made by a boundary facet and by a Delaunay cell to be splitted by the facet's affine hull. Here we show how to partition at each such cells into two cells, according to Figure 2, where the boundary facets of the two boolean arguments are shown in yellow color.

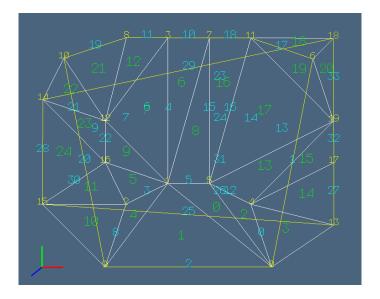

Figure 2: example caption

In the example in Figure 2, the set of pairs (facet,cell) to be used as splitting seeds are given below.

```
[[25, 3], [1, 3], [29, 18], [20, 22], [1, 19], [25, 10], [20, 10], [29, 22]]
```

### 4.1 Cell splitting

A cell will be split by pyplasm intersection with a suitable rotated and translated instance of a (large) d-cuboid with the superior face embedded in the hyperplane z = 0.

Splitting a cell with an hyperplane The macro below defines a function cellSplitting, with input the index of the face, the index of the cell to be bisected, the covector giving the coefficients of the splitting hyperplane, i.e. the affine hull of the splitting face, and the arrays V, EEV, CV, giving the coordinates of vertices, the (accumulated) facet to vertices relation (on the input models), and the cell to vertices relation (on the Delaunay model), respectively.

The actual subdivision of the input cell onto the two output cells cell1 and cell2 is performed by using the pyplasm Boolean operations of intersection and difference of the input with a solid simulation of the needed hyperspace, provided by the rototranslSubspace variable. Of course, such pyplasm operators return two Hpc values, whose vertices will then extracted using the UKPOL primitive.

```
\langle \text{ Cell splitting } 10 \rangle \equiv
     """ Cell splitting in two cells """
     def cellSplitting(face,cell,covector,V,EEV,CV):
        print "\nV,CV =",V,CV
        dim = len(V[0])
        subspace = (T(range(1,dim+1))(dim*[-50])(CUBOID(dim*[100])))
        normal = covector[:-1]
        if len(normal) == 2: # 2D complex
           rotatedSubspace = R([1,2])(ATAN2(normal)-PI/2)(T(2)(-50)(subspace))
        elif len(normal) == 3: # 3D complex
           rotatedSubspace = R()()(subspace)
        else: print "rotation error"
        t = V[EEV[face][0]]
        rototranslSubspace = T(range(1,dim+1))(t)(rotatedSubspace)
        cellHpc = MKPOL([V,[[v+1 for v in CV[cell]]],None])
        # cell1 = INTERSECTION([cellHpc,rototranslSubspace])
        tolerance=0.0001
        use_octree=False
        cell1 = Plasm.boolop(BOOL_CODE_AND,
           [cellHpc,rototranslSubspace],tolerance,plasm_config.maxnumtry(),use_octree)
        verts,cells,pols = UKPOL(cell1)
        cell1 = AA(vcode)(verts)
        # cell2 = DIFFERENCE([cellHpc,rototranslSubspace])
        cell2 = Plasm.boolop(BOOL_CODE_DIFF,
           [cellHpc,rototranslSubspace],tolerance,plasm_config.maxnumtry(),use_octree)
        verts,cells,pols = UKPOL(cell2)
        cell2 = AA(vcode)(verts)
        return cell1,cell2
Macro referenced in 16b.
```

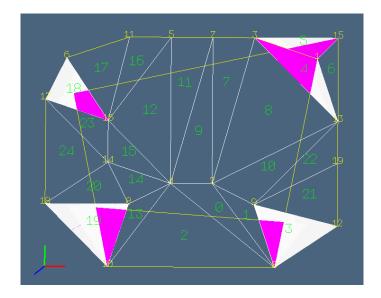

Figure 3: example caption

### 4.2 Cross-building of two task dictionaries

The correct and efficient splitting of the combined Delaunay complex (CDC) with the (closed and orientable) boundaries of two Boolean arguments, requires the use of two special dictionaries, respectively named dict\_fc (for face-cell), and dict\_cf (for cell-face).

On one side, for each splitting facet ((d-1)-face), used as key, we store in dict\_fc the list of traversed d-cells of CDC, starting in 2D with the two cells containing the two extreme vertices of the cutting edge, and in higher dimensions, with all the d-cells containing one of vertices of the splitting (d-1)-face.

On the other side, for each d-cell to be split, used as key, we store in  $dict_cf$  the list of cutting (d-1)-cells, since a single d-cell may be traversed and split by more than one facet.

#### Init face-cell and cell-face dictionaries

```
⟨Init face-cell and cell-face dictionaries 12a⟩ ≡
    """ Init face-cell and cell-face dictionaries """
    def initTasks(tasks):
        dict_fc = defaultdict(list)
        dict_cf = defaultdict(list)
        for task in tasks:
            face,cell,covector = task
            dict_fc[face] += [(cell,covector)]
            dict_cf[cell] += [(face,covector)]
```

```
return dict_fc,dict_cf
```

#### Example of face-cell and cell-face dictionaries

```
\langle Example of face-cell and cell-face dictionaries 12b\rangle \equiv
     """ Example of face-cell and cell-face dictionaries """
     tasks (face,cell) = [
      [0, 4, [-10.0, 2.0, 110.0]],
      [31, 5, [3.0, -14.0, 112.0]],
      [17, 18, [10.0, 2.0, -30.0]],

       4: [(0, [-10.0, 2.0, 110.0])],
       5: [(31, [3.0, -14.0, 112.0])] })
     \Diamond
```

Macro never referenced.

#### 4.3 Updating the vertex set and dictionary

In any dimension, the split of a d-cell with an hyperplane (crossing its interior) produces two d-cells and some new vertices living upon the splitting hyperplane.

When the d-cell c is contained in only one seed of the CDC decomposition, i.e. when  $dict_cf[c]$  has cardinality one (in other words: it is crossed only by one boundary facet), the two generated cells vcell1,vcell2 can be safely output, and accommodated in two slots of the CV list.

Conversely, when more than one facet crosses c, much more care must be taken to guarantee the correct fragmentation of this cell.

Managing the splitting dictionaries The function splittingControl takes care of cells that must be split several times, as crossed by several boundary faces.

If the dictionary item dict\_cf[cell] has *length* one (i.e. is crossed *only* by one face) the CV list is updated and the function returns, in order to update the dict\_fc dictionary.

Otherwise, the function subdivides the facets cutting cell between those to be associated to vcell1 and to vcell2. For each pair aface, covector in dict\_cf[cell] and in position following face in the list of pairs, check if either vcell1 or vcell2 or both, have intersection with the subset of vertices shared between cell and aface, and respectively put in alist1, in alist2, or in both. Finally, store vcell1 and vcell2 in CV, and alist1, alist2 in dict\_cf.

```
TODO: update dict_fc ...
\langle Managing the splitting dictionaries 13\rangle \equiv
     """ Managing the splitting dictionaries """
     def splittingControl(face,cell,vcell1,vcell2,dict_fc,dict_cf,V,EEV,CV,VC):
        # only one facet covector crossing the cell
        print "**** 1"
        cellVerts = CV[cell]
        print "cellVerts =",cellVerts
        CV[cell] = vcell1
        CV += [vcel12]
        covector = dict_cf[cell][0][1]
        dict_fc[face].remove((cell,covector)) # remove the split cell
        dict_cf[cell].remove((face,covector)) # remove the splitting face
        print "dict_fc =",dict_fc
        print "dict_cf =",dict_cf
        # more than one facet covectors crossing the cell
        print "**** 2"
        alist1,alist2 = list(),list()
        print "alist1,alist2 =",alist1,alist2
        for aface,covector in dict_cf[cell]:
           # for each facet crossing the cell
           # compute the intersection between the facet and the cell
           print "**** 3"
           print "aface,covector =",aface,covector
           faceVerts = EEV[aface]
           print "faceVerts =",faceVerts
```

```

# 4.4 Updating the split cell and the stack of seeds

When a d-cell of the combined Delaunay complex (CDC) is split into two d-cells, the first task to perform is to update its representation as vertex list, and to update the list of d-cells. In particular, as cell, and cell1, cell2 are the input d-cell and the two output d-cells, respectively, we go to substitute cell with cell1, and to add the cell2 as a new row of the CSR( $M_d$ ) matrix, i.e. as the new terminal element of the CV array. Of course, the reverse relation VC must be updated too.

Updating the split cell First of all notice that, whereas cell is given as an integer index to a CV row, cell1, cell2 are returned by the cellSplitting function as lists of lists of coordinates (of vertices). Therefore such vectors must be suitably transformed into dictionary keys, in order to return the corresponding vertex indices. When transformed into two lists of vector indices, cell1, cell2 will be in the form needed to update the CV and VC relations.

```
⟨Updating the split cell 16a⟩ ≡

""" Updating the split cell """

def splitCellUpdate(cell,vcell1,vcell2,CV):
    print "cell,vcell1,vcell2 =",cell,vcell1,vcell2
    newVerts = list(set(vcell1).difference(CV[cell]))
    return newVerts

# 4.5 Updating the cells adjacent to the split cell

Once the list of d-cells has been updated with respect to the results of a split operation, it is necessary to consider the possible update of all the cells that are adjacent to the split one. It particular we need to update their lists of vertices, introducing the new vertices produced by the split.
