# Accelerated intersection of geometric objects \*

# Alberto Paoluzzi

# April 13, 2016

#### Abstract

This module contains the first experiments of a parallel implementation of the intersection of (multidimensional) geometric objects. The first installment is being oriented to the intersection of line segment in the 2D plane. A generalization of the algorithm, based on the classification of the containment boxes of the geometric values, will follow quickly.

# 1 Introduction

An easily parallelizable implementation of the accelerated intersection of geometric objects is given in this module. Our first aim is to implement a specialized version for simplices, that generalizes the nD-trees of points (that are 0-simplices), to (d-1)-dimensional simplices in d-space, starting with the intersection of line segments in the plane. Our plan is to follow with an implementation for intersection of general  $non\ convex$  sets.

# 2 Implementation

The first implementation of this module concerns the computation of the intersection points among a set of line segment in the 2D plane. The containment boxes of the input segments are iteratively classified against the 1-dimensional centroid of smaller and smaller buckets of data.

At the end of the classification, where the same geometric object may be inserted in several different buckets, a *brute-force* intersection is applied to each final subset. Finally, the duplicated intersection points are removed, and a 1-dimensional LAR data structure is generated, with 1-cells given by the split line segments.

A complete LAR of the plane partition generated by the arrangment of lines is then computed by: (a) generating the maximal 2-connected components of such 1-dimensional graph; and (b) by traversing in counter-clockwise order the generated subgraphs to report the 2-dimensional cells of the plane partition.

The splitting algorithm may be easily parallelized, since both during their generation and at the end of this one, the various buckets of data can be dispatched to different processors for independent computation, followed by elimination of duplicates. In particular, a standard *map-reduce* software infrastructure may be used for this parallelization purpose.

## 2.1 Construction of independent buckets

Containment boxes Given as input a list randomLineArray of pairs of 2D points, the function containment2DBoxes returns, in the same order, the list of containment boxes of the input lines. A containment box of a geometric object of dimension d is defined as the minimal d-cuboid, equioriented with the reference frame, that contains the object. For a 2D line it is given by the tuple (x1, y1, x2, y2), where (x1, y1) is the point of minimal coordinates, and (x2, y2) is the point of maximal coordinates.

```
⟨Containment boxes 2a⟩ ≡

""" Containment boxes """

def containment2DBoxes(randomLineArray):
    boxes = [eval(vcode(4)([min(x1,x2),min(y1,y2),max(x1,x2),max(y1,y2)]))
        for ((x1,y1),(x2,y2)) in randomLineArray]

return boxes

```

## 2.3 Generation of LAR representation of split segments

The function lines2lar is used to generate a 1-dimensional LAR complex from an array of lines, i.e. of pairs of 2D points. For every *line* in frags is computed an *ordered* list outline of *symbolic* intersection points, including the first and last vertex of the line, and every interior point generated by the list params[k].

Then, for every symbolic representation key of a point in outline, a dictionary vertex is either created or retrieved, and a corresponding edge is orderly created, using the index of the point. At the same time, the vertices created in this way are accumulated within the V array. Finally, each edge in EV is extended to contain a second vertex index using the subsequent edge.

The third stage finalizes the vertex set of the output LAR, by identifying the closest vertices, i.e. those at distance less or equal to the current resolution, set to 10\*\*(-PRECISION), by searching via the scipy.spatialKDTree the pairs of vertices at less than this distance.

A fourth stage identifies the possibly duplicated edges. Some of these could appear, e.g., when importing a set of adjacent boxes from some drawing program, to generate an array of lines, to be mutually intersected and transformed into a LAR data structure.

#### Create the LAR of fragmented lines

```
⟨ Create the LAR of fragmented lines 6⟩ ≡
    """ Create the LAR of fragmented lines """
    from scipy import spatial

#### 2.5 2D cells from biconnected components

It is very easy, using the LAR representation of topology, to compute the 2-cells of the plane partitions (see Figures 1b and 1c) induced by the biconnected components extracted from a graph (1-complex).

In particular, let us consider the CSR (Compressed Sparse Row) representation of the characteristic matrix  $M_1$ , here usually denoted as EV, in order to remark that we represent the edges on the rows, and the vertices on the columns of the matrix. As such it is a binary matrix. So, we can readily reconstruct the topology of 2-cells by associating to each non-zero (sparse) matrix element  $\mathtt{angle}.\mathsf{EV}(h,k)$  the angle in radians that the edge  $e_h$  forms with the orizontal line, when it incides on the vertex  $v_k$ .

Of course, if  $e_h = (v_{k_1}, v_{k_2})$ , then it will be

```
{\tt angle\_EV}(h,k_2) = {\tt angle\_EV}(h,k_1) + \pi = -{\tt angle\_EV}(h,k_1)
```

Figure 1: Two random line arrangements, and the biconnected components extracted by their LAR 1-complexes.

Therefore, the columns of angle\_EV, i.e. the rows of angle\_VE := angle\_EV<sup>t</sup>, after being sorted on their angles  $\alpha$ , and associated with the angle differences  $\Delta \alpha$ , will provide a basis of elementary 1-cochains that evaluate to zero for each closed 1-cochain, i.e. for every cycle supported by the linear space of 1-chains on the given line arrangement.

#### Slope of edges

#### Circular ordering of edges around vertices

```
\langle Slope of edges 9 \rangle \equiv
     """ Circular ordering of edges around vertices """
     def edgeSlopeOrdering(model):
         V, EV = model
         VE, VE_angle = invertRelation(EV),[]
         for v,ve in enumerate(VE):
              ve_angle = []
             if ve != []:
                  for edge in ve:
                      v0,v1 = EV[edge]
                                     x,y = list(array(V[v1]) - array(V[v0]))
                      if v == v0:
                      elif v == v1:
                                       x,y = list(array(V[v0]) - array(V[v1]))
                      angle = math.atan2(y,x)
                      ve_angle += [180*angle/PI]
              pairs = sorted(zip(ve_angle,ve))
              #VE_angle += [TRANS(pairs)[1]]
              VE_angle += [[pair[1] for pair in pairs]]
         return VE_angle
```

Macro referenced in 19.

Ordered incidence relationship vertices to edges. As we have seen, the VE\_angle list of lists reports, for every vertex in V, the list of incident edges, counterclockwise ordered around the vertex. Therefore the ordered\_csrVE function, given below, returns the "compressed sparse row" matrix, row-indexed by vertices and column-indexed by edges, and such that in position (v,e) contains the index  $\ell$  of the next edge (after e, say) in the counterclockwise ordering of edges around v.

```
⟨ Ordered incidence relationship of vertices and edges 11a⟩ ≡

""" Ordered incidence relationship of vertices and edges """

def ordered_csrVE(VE_angle):
    triples = []
    for v,ve in enumerate(VE_angle):
        n = len(ve)
        for k,edge in enumerate(ve):
```

```
triples += [[v, ve[k], ve[ (k+1)%n ]]]
csrVE = triples2mat(triples,shape="csr")
return csrVE
```

Faces from biconnected components Since edges in the plane partition induced by a line arrangement are (d-1)-cells, they are located on the boundary of  $two\ d$ -cells (faces) of the partition. Hence, the traversal algorithm of the data structure storing the relevant information may be driven by signing the two extremes (vertices) of each edge as either already visited or not.

```
\langle Faces from biconnected components 11b\rangle \equiv
     """ Faces from biconnected components """
     def firstSearch(visited):
         for edge,vertices in enumerate(visited):
             for v,vertex in enumerate(vertices):

```

**Txample** The ordered csrVE (vertex-edge) matrix generated by the example of file test/py/inters/test07.py is shown in dense format in the example script below. Let us notice the each non-zero element csrVE(k,h) stores the index of the previous edge inciding on the vertex  $v_k$  before the edge  $e_h$ . The traversal of the data structure is made accordingly, in order to extract the vertices of all the faces (minimal edge cycles) generated by a line arrangement in the plane.

 $\langle$  Example of VE matrix with nextEdge indices 13a $\rangle$   $\equiv$ 

```
csr2DenseMatrix(csrVE)
>>> array([
     [12,
                0,

#### 2.6 Transformation of an array of lines in a 2D LAR complex

Transformation of an array of lines in a 2D LAR complex The whole transformation of an array of lines into a two-dimensional LAR complex is executed by the function larFromLines. The function returns the model triple V, FV, EV. The last element in FV is the *ordered* boundary chain. just notice that

⟨Transformation of an array of lines in a 2D LAR complex 13b⟩ ≡

""" Transformation of an array of lines in a 2D LAR complex """

def larFromLines(lines):
 def larPairSimplify((V,EV)):
 V,EVs = biconnectedComponent((V,EV))
 EV = CAT(EVs)
 V,EV = larRemoveVertices(V,EV)
 return V,EV

V,EV = lines2lar(lines)
 V,EV = larPairSimplify((V,EV)) #TODO: toggle to check the generated FV
 V,polygons,EV = larPair2Triple((V,EV))
 FV = AA(list)(AA(set)(AA(CAT)(polygons)))
 return V,FV,EV,polygons

◇

2.7 Pruning LAR models from parts out of proper resolution

Macro referenced in 19.

# Pruning of clusters of too close vertices is executed by taking a LAR model as input,

Pruning of clusters of too close vertices is executed by taking a LAR model as input, executing the following computations, and producing a new simplified LAR model.

Pruning away clusters of close vertices First, reduce the array of vertices pts to its quotient set with respect to the transitive closure of the relation of "nearness". Two vertices are "near" when their (Euclidean) distance is less than a given RADIUS. The subgraphs of the graph of this relation are contracted in a single point, set to the centroid of the vertices of the subgraph. The function W takes as input the array pts of vertex points, and returns: (a) the array newV of new vertices; (b) the list of lists close of sorted indices of pairs of close vertices, removed from duplicates; (c) the list of clusters of pts indices; (d) the integer vmap array, mapping old vertex indices to new vertex indices.

```
\langle Pruning away clusters of close vertices 14\rangle \equiv """ Pruning away clusters of close vertices """ from scipy.spatial import cKDTree def pruneVertices(pts,radius=0.001):
```

```
tree = cKDTree(pts)
a = cKDTree.sparse_distance_matrix(tree,tree,radius)
#print a.keys()
close = list(set(AA(tuple)(AA(sorted)(a.keys()))))
import networkx as nx
G=nx.Graph()
G.add_nodes_from(range(len(pts)))
G.add_edges_from(close)
clusters, k, h = [], 0, 0
subgraphs = list(nx.connected_component_subgraphs(G))
V = [None for subgraph in subgraphs]
vmap = [None for k in xrange(len(pts))]
for k, subgraph in enumerate(subgraphs):
    group = subgraph.nodes()
    if len(group)>1:
        V[k] = CCOMB([pts[v] for v in group])
        for v in group: vmap[v] = k
        clusters += [group]
    else:
        oldNode = group[0]
        V[k] = pts[oldNode]
        vmap[oldNode] = k
return V, close, clusters, vmap
```

**Export a simplified LAR model** Next, update the arrays of compressed characteristic matrices of a Linear Algebraic Representation. The standard approach is to read row-wise the arrays of matrices of incidence of cells on vertices; translate every index using the vmap array, mapping old vertex indices to new ones; remove repeated indices and substitute them with a single instance; check if the new index list has length greater or equal to the number of vertices of the simplex of the proper dimension. Finally, write an output cell if and only if the previous test is true.

```
⟨Return a simplified LAR model 15⟩ ≡

""" Return a simplified LAR model """

def larSimplify(model,radius=0.001):
    if len(model)==2: V,CV = model
    elif len(model)==3: V,CV,FV = model
    else: print "ERROR: model input"

W,close,clusters,vmap = pruneVertices(V,radius)
    celldim = DIM(MKPOL([V,[[v+1 for v in CV[0]]],None]))
    newCV = [list(set([vmap[v] for v in cell])) for cell in CV]
```

```
CV = list(set([tuple(sorted(cell)) for cell in newCV if len(cell) >= celldim+1]))
CV = sorted(CV,key=len) # to get the boundary cell as last one (in most cases)

if len(model)==3:
    celldim = DIM(MKPOL([V,[[v+1 for v in FV[0]]],None]))
    newFV = [list(set([vmap[v] for v in facet])) for facet in FV]
    FV = [facet for facet in newFV if len(facet) >= celldim]
    FV = list(set(AA(tuple)(AA(sorted)(FV))))
    return W,CV,FV
else: return W,CV
```

Test of pruning clusters of close vertices Here a list of random 2D points is generated. Then the set of vertices is pruned by updating it to its quotient set with respect to the transitive closure of a relation of "nearness" within an Euclidean distance of given RADIUS. The pruning of vertices is performed by the pruneVertices function, with input the array pts of points. The dictionary vmap

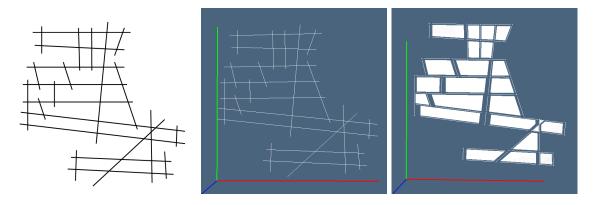

Figure 6: LAR complex generation from SVG file. (a) the input set of lines; (b) imported in pyplasm environment; (c) the extracted regularized 2-complex, drawn exploded.

Simplified SVG parsing and normalization The easiest method for the input of SVG primitives, to be transformed into a *line soup*, in order to subsiquently generate a 2D cellular complex, mainly oriented to sudent use, is to drag a SVG file into the input window of the web service <a href="http://cvdlab.github.io/svg2lines">http://cvdlab.github.io/svg2lines</a>. The file is transformed into quadruples of comma-separated numbers, each corresponding to the pair of extreme point coordinates of a line. This text may be saved into a text file, possibly decorated with the suffix .lines, to be read and normalized into the coordinate space  $[0,1] \times [0,1]$  by the following function lines2lines, and then used by other larlib functions (for example, by lines2lar (see test/py/inters/test10.py).

```
⟨Simplified SVG parsing and normalization 27a⟩ ≡
    """ Simplified SVG parsing and normalization """
    def lines2lines(filename):
        stringLines = [line.strip() for line in open(filename)]
```

```
lines = [AA(eval)(string.split(',')) for string in stringLines]
lines = [[[x1,y1],[x2,y2]] for x1,y1,x2,y2 in lines]

\(SVG input normalization transformation 28)

containmentBox = box
return lines
```

**SVG** input parsing and transformation We postulate here that the input file test/py/inters/test.svg should contain only primitives, so we skip any other content. Such primitives are parsed by matching against regular expressions, and their x1,y1,x2,y2 attributes are extracted and stored into the lines variable. An isomorphic window-viewport transformation is then performed, to transform the data within the standard unit 2D square [0, 1]<sup>2</sup>. The input vertices are finally set to a fixed resolution, using the vcode(4) function.

```

**2-complex extraction from svg file** The input lines arrangments produces a 1-dimensional complex stored into the LAR model V, EV. Then the *dangling edges* are removed from EV\_, and the whole data set is renumbered, in order to remove the unused vertices,

using the larRemoveVertices function. Finally the 2-cells are computed and stored in FV, and the positive areas of every 2cells are computed, so allowing for identify and removal of the exterior face, corresponding to the boundary of the complex. The polygonal boundary of the complex is finally drawn.

#### A Code utilities

**Coding utilities** Some utility fuctions used by the module are collected in this appendix. Their macro names can be seen in the below script.

```
⟨ Coding utilities 32a⟩ ≡

""" Coding utilities """

⟨ Generation of all binary subsets of length n 32b⟩

⟨ Generation of a random point 33a⟩

⟨ Generation of a random line segment 33b⟩

⟨ Transformation of a 2D box into a closed polyline 33c⟩

⟨ Computation of the 1D centroid of a list of 2D boxes 34a⟩
```

```
\langle Pyplasm XOR of FAN of ordered points 34b \rangle \diamond Macro referenced in 19.
```

#### Generation of all binary subsets of lenght n

Macro referenced in 32a.

### Example

```
In [9]: allBinarySubsetsOfLenght(3)
Out[9]: [[0,0,1],[0,1,0],[0,1,1],[1,0,0],[1,0,1],[1,1,0],[1,1,1]]
```

Generation of random lines The function randomLines returns the array randomLineArray with a given number of lines generated within the unit 2D interval. The scaling parameter is used to scale every such line, generated by two randow points, that could be possibly located to far from each other, even at the distance of the diagonal of the unit square.

The arrays xs and ys, that contain the x and y coordinates of line points, are used to compute the minimal translation v needed to transport the entire set of data within the positive quadrant of the 2D plane.

```
⟨Generation of random lines 32c⟩ ≡
    """ Generation of random lines """

def randomLines(numberOfLines=200,scaling=0.3):
    randomLineArray = [redge(scaling) for k in range(numberOfLines)]
    [xs,ys] = TRANS(CAT(randomLineArray))[:2]
    xmin, ymin = min(xs), min(ys)
    v = array([-xmin,-ymin])
    randomLineArray = [[list(v1[:2]+v), list(v2[:2]+v)] for v1,v2 in randomLineArray]
    return randomLineArray
```

Macro referenced in 19.

Generation of a random point A single random point, codified in floating point format, and with a fixed (quite small) number of digits, is returned by the rpoint2d() function, with no input parameters.

Generation of a random line segment A single random segment, scaled about its centroid by the scaling parameter, is returned by the redge() function, as a tuple of two random points in the unit square.

```
⟨Generation of a random line segment 33b⟩ ≡
    """ Generation of a random line segment """

def redge(scaling):
    v1,v2 = array(rpoint2d()), array(rpoint2d())
    c = (v1+v2)/2
    pos = rpoint2d()
    v1 = (v1-c)*scaling + pos
    v2 = (v2-c)*scaling + pos
    return tuple(eval(vcode(4)(v1))), tuple(eval(vcode(4)(v2)))
    ◊
Macro referenced in 32a.
```

Transformation of a 2D box into a closed polyline The transformation of a 2D box into a closed rectangular polyline, given as an ordered sequence of 2D points, is produced by the function box2rect

```
⟨Transformation of a 2D box into a closed polyline 33c⟩ ≡
    """ Transformation of a 2D box into a closed polyline """
    def box2rect(box):
        x1,y1,x2,y2 = box
        verts = [[x1,y1],[x2,y1],[x2,y2],[x1,y2],[x1,y1]]
        return verts
```

Macro referenced in 32a.

Computation of the 1D centroid of a list of 2D boxes The 1D centroid of a list of 2D boxes is computed by the function given below. The direction of computation (either x or y) is chosen depending on the value of the xy parameter.

```
⟨ Computation of the 1D centroid of a list of 2D boxes 34a⟩ ≡
    """ Computation of the 1D centroid of a list of 2D boxes """
    def centroid(boxes,coord):
        delta,n = 0,len(boxes)
        ncoords = len(boxes[0])/2
        a = coord%ncoords
        b = a+ncoords
        for box in boxes:
            delta += (box[a] + box[b])/2
        return delta/n
```

Macro referenced in 32a.

#### Pyplasm XOR of FAN of ordered points

```
⟨Pyplasm XOR of FAN of ordered points 34b⟩ ≡
    """ XOR of FAN of ordered points """

def FAN(points):
    pairs = zip(points[1:-2],points[2:-1])
    triangles = [MKPOL([[points[0],p1,p2],[[1,2,3]],None]) for p1,p2 in pairs]
    return XOR(triangles)
