Boolean combinations of cellular complexes as chain operations *

Alberto Paoluzzi

November 6, 2014

---

1 Introduction

In this module a novel approach to Boolean operations of cellular complexes is defined and implemented. The novel algorithm may be summarised as follows.

First we compute the CDC (Common Delaunay Complex) of the input LAR complexes A and B, to get a LAR of the *simplicial* CDC.

Then, we split the cells intersecting the boundary faces of the input complexes, getting the final *polytopal* SCDC (Split Common Delaunay Complex), whose cells provide the basis for the linear coordinate representation of both input complexes, upon the same space decomposition.

Afterwards, every Boolean result is computed by bitwise operations, between the coordinate representations of the transformed A and B input.

Finally a greedy assembly of SCDC cells is executed, in order to return a polytopal complex with a reduced number of cells.

1.1 Preview of the Boolean algorithm

The goal is the computation of $A \diamond B$, with $\diamond \in \{\cup, \cap, -\}$, where a LAR representation of both A and B is given. The Boolean algorithm works as follows.

1. Embed both cellular complexes A and B in the same space (say, identify their common vertices) by $V_{ab} = V_a \cup V_b$.

2. Build their CDC (Common Delaunay Complex) as the LAR of *Delaunay triangulation* of the vertex set V_{ab}, and embedded ∂A and ∂B in it.

3. Split the (highest-dimensional) cells of CDC crossed by ∂A or ∂B. Their lower dimensional faces remain partitioned accordingly. We name the resulting complex SCDC (Split Common Delaunay Complex).

4. With respect to the SCDC basis of d-cells C_d, compute two coordinate chains $\alpha, \beta :$ $C_d \to \{0, 1\}$, such that:

$$\alpha(cell) = 1 \quad \text{if } |cell| \subset A; \quad \text{else } \alpha(cell) = 0,$$
$$\beta(cell) = 1 \quad \text{if } |cell| \subset B; \quad \text{else } \beta(cell) = 0.$$

5. Extract accordingly the SCDC chain corresponding to $A \diamond B$, with $\diamond \in \{\cup, \cap, -\}$.

1.2   Remarks

You may make an analogy between the SCDC (*Split* CDC) and a CDT (Constrained Delaunay Triangulation). In part they coincide, but in general, the SCDC is a polytopal complex, and is not a simplicial complex as the CDC.

The more complex algorithmic step is the cell splitting. Every time, a single d-cell c is split by a single hyperplane (cutting its interior) giving either two splitted cells c_1 and c_2, or just one output cell (if the hyperplane is the affine hull of the CDC facet) whatever the input cell dimension d. After every splitting of the cell interior, the row c is substituted (within the CV matrix) by c_1, and c_2 is added to the end of the CV matrix, as a new row.

The splitting process is started by "splitting seeds" generated by $(d-1)$-faces of both operand boundaries. In fact, every such face, say f, has vertices on CDC and *may* split some incident CDC d-cell. In particular, starting from its vertices, f must split the CDC cells in whose interior it passes though.

So, a dynamic data structure is set-up, storing for each boundary face f the list of cells it must cut, and, for every CDC d-cell with interior traversed by some such f, the list of cutting faces. This data structure is continuously updated during the splitting process, using the adjacent cells of the split ones, who are to be split in turn. Every split cell may add some adjacent cell to be split, and after the split, the used pair (`cell,face`) is removed. The splitting process continues until the data structure becomes empty.

Every time a cell is split, it is characterized as either internal (1) or external (0) to the used (oriented) boundary facet f, so that the two resulting subcells c_1 and c_2 receive two opposite characterization (with respect to the considered boundary).

At the very end, every (polytopal) SCDC d-cell has two bits of information (one for argument A and one for argument B), telling whether it is internal (1) or external (0) or unknown (-1) with respect to every Boolean argument.

A final recursive traversal of the SCDC, based on cell adjacencies, transforms every -1 into either 0 or 1, providing the two final chains to be bitwise operated, depending on the Boolean operation to execute.

2 Step 1: merging discrete spaces

2.1 Requirements

The *join* of two sets $P, Q \subset \mathbb{E}^d$ is the set $PQ = \{\alpha \mathbf{x} + \beta \mathbf{y} \,|\, \mathbf{x} \in P, \ \mathbf{y} \in Q\}$, where $\alpha, \beta \in \mathbb{R}$, $\alpha, \beta \geq 0$, and $\alpha + \beta = 1$. The join operation is associative and commutative.

Input Two LAR models of two non-empty "solid" d-spaces A and B, denoted as `(V1,CV1)` and `(V2,CV2)`.

Output The LAR representation `(V,CV)` of Delaunay triangulation (simplicial d-complex) of the set conv $AB \subset \mathbb{E}^d$, convex hull of the join of A and B, named Common Delaunay Complex (CDC) in the following.

Auxiliary data structures This software module returns also:

1. a dictionary `vertDict` of `V` vertices, with *key* the symbolic representation of vertices v returned by expressions `vcode(v)`, $v \in V$, and with values the finite ordinal numbers of the vertices;

2. the numbers `n1`, `n12`, `n2` of the elements of `V1`, `V1` $\cap$ `V2`, and `V2`, respectively. Notice that the following assertions must hold (see Figure 1):

$$\texttt{n1} - \texttt{n12} + \texttt{n2} = \texttt{n} \tag{1}$$

$$0 < \texttt{n} - \texttt{n2} \leq \texttt{n1} < \texttt{n} \tag{2}$$

3. the input boundary complex `(V,BC)`, with `BC = BC1+BC2`, i.e. the union of the two boundary $(d-1)$-complexes `(V,BC1)` and `(V,BC2)`, defined on the common vertices.

3   Step 2: splitting cells

The goal of this section is to transform the CDC simplicial complex, into the polytopal
Split Common Delaunay Complex (SCDC), by splitting the d-cells of CDC crossed in their
interior by some cell of the input boundary complex.

3.1   Requirements

We call here for a sequential implementation, following every $(d-1)$-facet `lambda` in BC
(for *Boundary Cells*). We start the splitting with `COVECTOR(lambda)` from `cell`, one of
the CDC d-cells incident on a vertex of `lambda`, and continue the splitting on the d-cells
$(d-1)$-adjacent to `cell`, where (a) `COVECTOR(lambda)` either crosses the `cell`'s interior
or contains one of `cell`'s $(d-1)$-facets and (b) such that the intersection with `lambda` is
not empty, until the queue (or stack) of d-cells to intersect with `covector` is not empty.

Best computational strategy   First associate to each cutting facet the list of cells it
may cut; then execute all the cuts. In this way we can compute the adjacency matrix just
one time at the beginning of the procedure, and do not need to update it after every split.

Input   The output of previous algorithm stage.

Output   The LAR representation (`W,PW`) of the SCDC,

Auxiliary data structures   This software module returns also a dictionary `splitFacets`, with keys the input boundary faces and values the list of pairs(`covector,fragmentedFaces`).

3.2   Implementation

3.2.2   Detail functions

Computing the adjacent cells of a given cell   To perform this task we make only use of the `CV` list. In a more efficient implementation we should make direct use of the sparse adjacency matrix, to be dynamically updated together with the `CV` list. The computation of the adjacent d-cells of a single d-cell is given here by extracting a column of the `CSR`$(M_d \, M_d^t)$. This can be done by multiplying `CSR`(M_d) by its transposed row corresponding to the query d-cell.

⟨ Computing the adjacent cells of a given cell 7b ⟩ ≡

```
""" Computing the adjacent cells of a given cell """
def adjacencyQuery (V,CV):
    dim = len(V[0])
    csrCV =  csrCreate(CV)
    csrAdj = matrixProduct(csrCV,csrTranspose(csrCV))
    def adjacencyQuery0 (cell):
```

```
        nverts = len(CV[cell])
        cellAdjacencies = csrAdj.indices[csrAdj.indptr[cell]:csrAdj.indptr[cell+1]]
        return [acell for acell in cellAdjacencies if dim <= csrAdj[cell,acell] < nverts]
    return adjacencyQuery0
◇
```

Relational inversion (characteristic matrix transposition)   The operation could be executed by simple matrix transposition of the CSR (Compressed Sparse Row) representation of the sparse characteristic matrix $M_d \equiv$ CV. A simple relational inversion using Python lists is given here. The `invertRelation` function is given here, linear in the size of the CV list, where the complexity of each cell is constant and small in most cases.

⟨Characteristic matrix transposition 8a⟩ ≡
```
    """ Characteristic matrix transposition """
    def invertRelation(CV):
        def myMax(List):
            if List==[]: return -1
            else: return max(List)
        columnNumber = max(AA(myMax)(CV))+1
        VC = [[] for k in range(columnNumber)]
        for k,cell in enumerate(CV):
            for v in cell:
                VC[v] += [k]
        return VC
◇
```

Macro referenced in 29.

Computation of splitting tests   In order to compute, in the simplest and more general way, whether each of the two split d-cells is internal or external to the splitting boundary $d-1$-facet, it is necessary to consider the oriented covector ϕ (or one-form) canonically associated to the facet f by the covector representation theorem, i.e. the corresponding oriented hyperplane. In this case, the internal/external attribute of the split cell will be computed by evaluating the pairing $< v, \phi >$.

⟨Splitting tests 8b⟩ ≡
```
    """ Splitting tests """
    def testingSubspace(V,covector):
        def testingSubspace0(vcell):
            inout = SIGN(sum([INNERPROD([[1.]+V[v],covector]) for v in vcell]))
            return inout
        return testingSubspace0
```

```
def cuttingTest(covector,polytope,V):
    signs = [INNERPROD([covector, [1.]+V[v]]) for v in polytope]

Elementary splitting test   Let us remember that the adjacency matrix between d-cells is computed via SpMSpM multiplication by the double application

$$\texttt{adjacencyQuery(V,CV)(cell)},$$

where the first application `adjacencyQuery(V,CV)` returns a partial function with bufferisation of the adjacency matrix, and the second application to `cell` returns the list of adjacent d-cells sharing with it a $(d-1)$-dimensional facet.

⟨ Elementary splitting test 9 ⟩ ≡

(True and True) or False

CDC cell splitting with one or more facets When splitting a d-cell with some
hyperplanes, we need to return not only either the two cut parts or the cell itself when
the hyperplane is tangent to a $(d-1)$-face, but also the facet lying on the hyperplane.
In the first cade it is directly computed by the SPLITCELL function, and returned as the
equal set of points. In the second case, the cell is transformed by the map that sends the
hyperplane in the $x_d = 0$ subspace ($z = 0$ in 3D), and the searched facet is returned as the
(back-transformed) set of cell vertices on this subspace.

Actually, the process is strongly complicated by the fact that the input cell (and its
facets) may be cut by several hyperplanes. By now, we resort to the simplest computation,
even if more time-expensive: to compare each vertex of each cell fragment, against every
hyperplanes. This approach will adapt well to the writing of a computational kernel on
the GPU.

⟨ CDC cell splitting with one or more cutting facets 10 ⟩ ≡
```
    """ CDC cell splitting with one or more cutting facets """
    # new implementation
    def fragment(cell,cellCuts,V,CV,BC):
        vcell = CV[cell]
        cellFragments = [[V[v] for v in vcell]]

        if cell==7 or cell==8:
            print "\nfragment >>"
            print "cell,cellCuts =",cell,cellCuts
            #stop()

        for f in cellCuts[cell]:
```

```
        facet = BC[f]

SCDC splitting with every boundary facet   The function `makeSCDC` is used to compute the LAR model (`W,CW`) of the SCDC. It takes as input the LAR model (`V,CV`) of the CDC, and the LAR model (`V,BC`) of the input Boolean Complex, and returns both a new LAR model (`W,CW`) and the vertex-cell relation `VC`, i.e. the transposed of `CV`.

For every k ∈ BC, a list `cellsToSplit`

The array `cellCuts` stores, for each cell in `CV`, the list of original boundary cells that will cut it, possibly by adjusting the `cellCuts` array length with empty lists. Therefore, the main loop in the `makeSCDC` function generates one or more cells in `CW`, starting from the k-th cell in `CV` and the k-th list `frags` in `cellCuts`.

4 Step 3: cell labeling

The goal of this stage is to label every cell of the SCDC with two bits, corresponding to the input spaces A and B, and telling whether the cell is either internal (1) or external (0) to either spaces.

4.1 Requirements

Input   The output of previous algorithmic stage.

Output   The array `cellLabels` with *shape* `len(PW)` $\times$ 2, and values in $\{0, 1\}$.

4.2 Implementation

The labelling of LAR of the SCDC may be decomposed in five consecutive steps. The first step was actually executed during the splitting stage, by accumulating a single facet of every split cells embedded on the affine hull (the covector hyperplane) of the splitting boundary `facet`. The second step provides the computation of the sparse matrix of the linear coboundary operator $\delta_{d-1} : C_{d-1} \to C_d$. The third step operates upon the previous two pieces of information, in order to compute the coboundary chain of the boundary chain of both input Boolean arguments. The fourth step attaches a IN/OUT label to each d-cell of the previously computed d-chain. Finally, the fifth step spreads around the labels to cover

17

all the d-cells of SCDC. This knowledge allows for the computation of every interesting Boolean expressions between the input complexes.

4.2.1 Summary

Coboundary operator on SCDC space decomposition   In this section we develop a stronger characterisation of the boundaries, by fully tagging in SCDC the internal coboundary of boundaries of A and B Boolean arguments. This novel strategy should allow the recursive tagging extension to work correctly in all cases.

As we know, the coboundary operators $\delta_{k-1} : C_{k-1} \to C_k$ are the transpose of the boundary operators $\partial_k : C_k \to C_{k-1}$ ($1 \le k \le d$). We therefore proceed to the construction of the operator δ_{d-1}, according to the procedure illustrated in []. For this purpose we need to use both the C_d and the C_{d-1} bases of SCDC. The first basis is generated as `CV` array during the splitting. The second basis will be built from C_d using the proper d-adjacency algorithm from [].

Let us remember that a (co)boundary operator may be applied to *any* chain from the linear space of chains defined upon a cellular complex. In our case we have already generated the $(d-1)$-chains ∂A and ∂B while building the SCDC, by accumulating, in the course of the splitting phase, the $(d-1)$-facets discovered while tracking the boundaries of A and B. We just need now to tag (a subset of) $\delta_{d-1}\partial_d A$ and $\delta_{d-1}\partial_d B$.

Computation of facets of a connected polytopal LAR model   The $(d-1)$-facets of a d-dimensional *polytopal and convex* LAR model are computed by the below `convexFacets` function by using both the algorithm codified by the function `larFacets` for the facets *internal* to the complex, *and* the `convexBoundary` algorithm for the facets on the convex boundary of the complex.

Conversely, the `larConvexFacets` function can be used to compute the $(d-1)$-facets of a possibly *non-connected and/or non-convex* polytopal complex.

Computation of boundary operator   The computation of the boundary operator ∂_d on the SCDC d-basis (W,CW) requires the knowledge of the $(d-1)$-basis (W,FW). The goal of this section is hence the—partially incremental—computation of FW. This set can be partitioned into *internal* cells, that have 2 cofaces, and *boundary* cells, that have only 1 coface. The first subset is easily computed by the larFacets function; the computation of the second subset requires some more work, specified in the following.

First, we compute the 0-chain of boundary vertices of the SCDC, using *qHull*, and take advantage of the CV matrix to extract the chain of d-cells sharing with the boundary a $(d-1)$facet. Second, using the *partial* boundary operator generated by using only the interior $(d-1)$-facets, and the associated $(d-2)$-boundary operator, we select the sub-chain made by the non-closed d-cells of this subset. Third, the boundary facet of each of them is finally selected, added to the $(d-1)$-basis of SCDC, and the corresponding row is added at the bottom line of the matrix of ∂_{d-1}.

5   Step 4: greedy cell gathering

The goal of this stage is to make as lower as possible the number of cells in the output LAR of the space AB, partitioned into convex cells.

Input   The LAR model `(W,PW)` of the SCDC and the array `cellLabels`.

Output   The LAR representation `(W,RW)` of the final fragmented and labeled space AB.

5.1   Requirements

The algorithm proposed here for d-cell gathering into bigger polytopes is local and greedy. Starting from an initial random d-cell, a $(d-1)$-connected d-chain is built, by attaching, one at a time, single cells to the boundary of the chain, after (local) verification that the support of the new chain will remain a convex set.

In case of failure of the test, the facets of the current chain boundary are checked for the gluing of their adjacent and external d-coface, until either a new convex is built, or no single cell can be attached convexly, so that the attachment process relative to that chain stops, and its boundary vertices are written in the LAR of a new complex, to gather a single new polytope generated by them.

Actually, during the stage of boundary checking for finding a new cocell to glue, only a subchain is checked, obtained by subtraction from the boundary of the cutting facets, where attachments are not possible, without violating the topology of Boolean results.

Two main algorithm components are needed here. The first one concerns the extraction of the current d-chain boundary, the subtraction from it of the splitting facets, and the selection of the facet where to glue another d-cell; the second one deals with the convexity test of the candidate (chain + boundary cocell) pair.

The local convexity test will extract, using the (co)boundary matrix of the current chain, the coboundary of the boundary of the candidate facet, and, selected the matrix of hyperplanes associated to it, will compute the centroid of the facet and the vector of signs exposed by the point transformed by right product with this matrix. The local test of convexity is satisfied if and only if all new vertices expose the same signs (or zero), when transformed by this matrix. In other words, the test is satisfied if all new vertices remain internal (or non external) to the cone generated by such set of boundary hyperplanes.

Every time that a new cell has been selected to join the current chain, the cell is also signed as already used, and hence as no more available for other choices. Of course, the algorithm terminates when all the input d-cells have been selected and signed.

5.2 Implementation

A synthetic view of the simplification process is given by the script below. The first tool provides a mapping from $(d-1)$-facets of SCDC to their embedding hyperplanes, i.e. to their affine hulls of codimension 1. The second one compute the boundary $(d-1)$-complex of the SCDC d-chain currently transformed into a single convex cell. The algorithmic bulk of the simplification process is contained in the script entitled `Sticking cells together`. The last script provides the high-level interface to transform the generated SCDC into a strongly simplified polytopal complex.

Building the complex of the current chain The function `chain2complex` returns the boundary complex of the current `chain`, minus the facet in `constraints`, where non d-cell may be attached to the current `chain`. It is computed via multiplication between the matrix of boundary operator and the coordinate representation `chainCoords` of `chain`. The `constraint` set is finally subtracted to the result.

$\langle$ Building the boundary complex of the current chain 23b $\rangle \equiv$

```
from scipy.sparse import csc_matrix
""" Building the boundary complex of the current chain """
def chain2complex(W,CW,chain,boundaryMat,constraints=[]):

Gathering and writing a polytopal complex   The task of the `gatherPolytopes`
function, given below, is to return the LAR `(X,CX)` of the SCDC `(W,CW)` generated by
the previous phases of the Boolean algorithm, after reducing its representation to a much
smaller size, (a) by gathering subsets of cells into single bigger polytopal cells within the
characteristic matrix `CX`, and (b) by assembling their boundary vertices into the (reduced)
vertex set `X`. Of course, while reducing the number of polytopal cells, the procedure should

26

not change the Boolean structure of the input complex, i.e. the support spaces $|C_A|, |C_B|$ of proper chains C_A and C_B and of their Boolean combinations.

⟨Gathering and writing a polytopal complex 25⟩ ≡

```
""" Gathering and writing a polytopal complex """
def gatherPolytopes(W,CW,FW,boundaryMat,bounds1,bounds2,CWbits):

5.2.3 Final removal of redundant vertices

After the simplification step, that replaces two or more convex d-cells with a single one cell, and the subsequent computation of the facets of the new cells, some vertices may become redundant, since are not intersection of at least d affine hulls supporting the $(d-1)$-facets.

Removal of redundant vertices from simplified LAR model The input to the function `larVertexRemoval` is the triple X, CX, FX of vertices, cells-by-vertices, and facets-by-vertices, where some of vertices may be redundant. Therefore, for each vertex, we compute the subset of incident facets, and then the subset of supporting covectors, i.e. the affine functions defining their affine hulls. If their number is greater or equal to the dimension of the embedding space, i.e. to the number of coordinates of vertices, then the vertex is non-redundant, and cannot be eliminated from the LAR model. If the vertex k is redundant, the corresponding value `X[k]` is substituted by the empty list. At the very end a rewriting vertex dictionary is generated and used to produce the novel output V, CV, and FV. Let us notice that the array `affineHullNumber` represents, for each vertex, the number of incident affine hulls. Hence, when `affineHullNumber[k]` is less that `dim`, the vertex `X[k]` is redundant, and can be eliminated.

⟨ Removal of redundant vertices from simplified LAR model 26 ⟩ ≡

```
""" Removal of redundant vertices from simplified LAR model """
def facetCovectors(X,FX):
    covectors = defaultdict(list)
    for k,facet in enumerate(FX):

9.1   Random data input

⟨ Random data input 43 ⟩ ≡

⟨ Generation of n random points in the unit d-disk 44a ⟩
⟨ Generation of n random points in the standard d-cuboid 44b ⟩
⟨ Triangulation of random points 44c ⟩
◇

Macro never referenced.

Random points in unit disk   First we generate a set of n random points in the unit D^d disk centred on the origin, to be subsequently used to generate a random Delaunay complex of variable granularity.

⟨ Generation of n random points in the unit d-disk 44a ⟩ ≡

```
def randomPointsInUnitCircle(n=200,d=2, r=1):
   points = random.random((n,d)) * ([2*math.pi]+[1]*(d-1))
   return [[SQRT(p[1])*COS(p[0]),SQRT(p[1])*SIN(p[0])] for p in points]
   ## TODO: correct for $d$-sphere

if __name__=="__main__":
   VIEW(STRUCT(AA(MK)(randomPointsInUnitCircle())))
◇
```

Macro referenced in 43.

Random points in the standard d-cuboid   A set of n random d-points is then generated within the standard d-cuboid, i.e. withing the d-dimensional interval with a vertex on the origin.

⟨ Generation of n random points in the standard d-cuboid 44b ⟩ ≡

```
def randomPointsInUnitCuboid(n=200,d=2):
   return random.random((n,d)).tolist()

if __name__=="__main__":
   VIEW(STRUCT(AA(MK)(randomPointsInUnitCuboid())))
◇
```

Macro referenced in 43.

Triangulation of random points   The Delaunay triangulation of `randomPointsInUnitCircle` is generated by the following macro.

⟨ Triangulation of random points 44c ⟩ ≡

```
from scipy.spatial import Delaunay
def randomTriangulation(n=200,d=2,out='disk'):
   if out == 'disk':
      V = randomPointsInUnitCircle(n,d)
   elif out == 'cuboid':
```

```
        V = randomPointsInUnitCuboid(n,d)
    CV = Delaunay(array(V)).vertices
    model = V,CV
    return model

if __name__=="__main__":
    from lar2psm import *
    VIEW(EXPLODE(1.5,1.5,1)(MKPOLS(model)))
